

Lab 5: Intro to stochastic models

NRES 470/670

Spring 2022

As ecologists, we work with ‘messy’ systems- we must therefore *embrace uncertainty*!!

In this lab we will continue to add complexity (and realism) to our population models in InsightMaker. Among the concepts we will explore are *parameter uncertainty*, *demographic stochasticity* and *environmental stochasticity*.

Here are the concepts we need for this lab (review!):

1. What if we don’t have enough data to specify our model (always the case!)? Another way of saying this is that we *lack sufficient knowledge* about key parameters or vital rates in our model. We can characterize this type of uncertainty by using **upper and lower bounds** (confidence intervals) that represent a range of plausible values for a particular vital rate. Some ways this uncertainty could be represented include:

$b = [1.1, 1.9]$ –or–

$b = 1.5 \pm 0.4$

The tool we use to deal with this type of uncertainty is called **uncertainty analysis**. In its simplest form, we run the model for the lower and upper extreme possible values (lower and upper bounds) and see what happens to our study system (e.g., does the population go extinct? decline?).

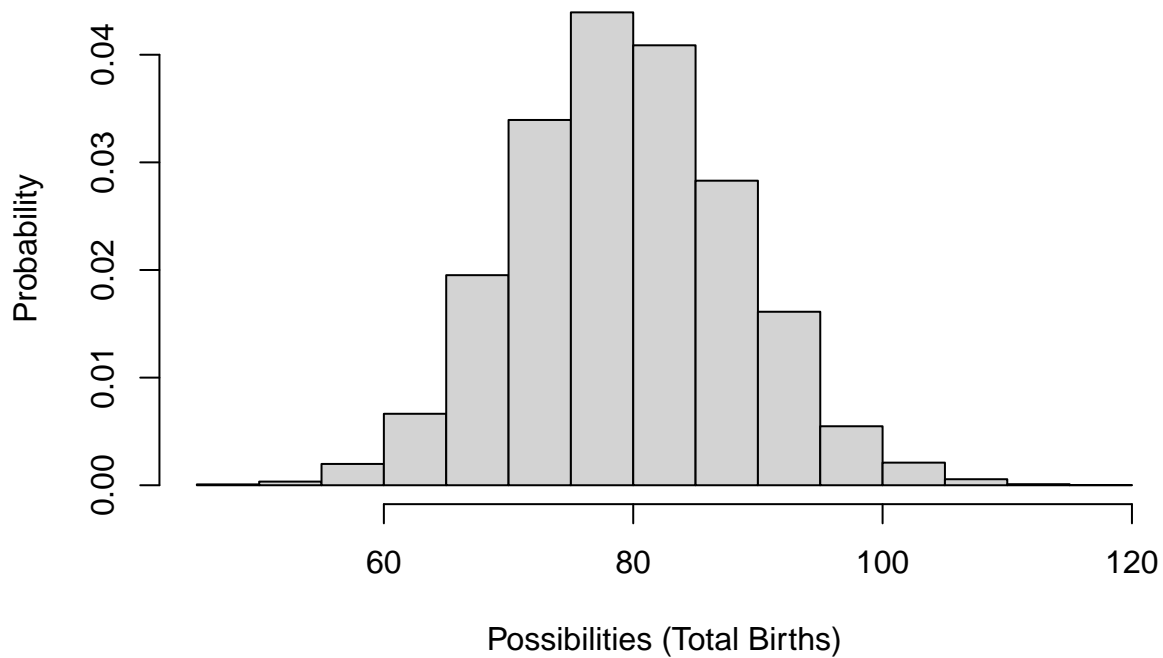

2. Second, we usually can’t predict whether an individual will live or die, breed or not breed, have females or males, have twins or triplets. In other words, we can’t predict whether an *individual* will be “lucky” or “unlucky”! We might know (with absolute certainty!) the per-capita *probability* of breeding, or the *probability* of dying, or the per-capita *rate* of offspring production, or the probability of a given offspring being female. But when it comes to projecting exactly who lives and dies, who gives birth and who doesn’t, how many females are born, we *just can’t know for sure*. In population ecology this type of uncertainty is called **demographic stochasticity**. In this case, the way we deal with this is we make the total number of births and deaths (the flows into and out of our stock[s]) **stochastic** – that is, we use a random-number generator!

For the total annual number of births in a population (the Births flow in InsightMaker), we usually use a **Poisson distribution**. The Poisson random number generator only produces whole numbers (we don’t like fractional individuals anyway) and doesn’t produce negative numbers. This makes it a good way to model births!

$$\text{Births} \sim \text{Poisson}(b * N_t) \quad (\text{Eq. 1})$$

For example, let’s imagine population size is 100 and the per-capita birth rate is exactly 0.8. Here is the *distribution* of Births (total annual number of births in the population):

```
#####  
# Review random number generators:  
  
# Poisson distribution  
  
hist(rpois(10000,(100*0.8)),main="",freq = F,ylab="Probability",xlab="Possibilities (Total Births)")
```

The total number of deaths in a population each year (the Deaths flow in InsightMaker) is usually modeled using a **Binomial distribution**. The Binomial random number generator only produces whole numbers (which we like- again, no fractional individuals!) and can only produce numbers that are greater than or equal to 0 and less than or equal to the total population size. These properties make it good for estimating total number of annual mortality or survival events!

$$Deaths \sim Binomial(size = N_t, prob = d) \quad (\text{Eq. 2})$$

Let's imagine population size is 100 and per-capita death rate is exactly 0.2. Here is the *distribution* of possible values for the total deaths in this population:

```
# Binomial distribution
```

```
hist(rbinom(10000,100,0.2),main="",xlab="Possibilities (Total Deaths)",freq = F,ylab="Probability")
```

- Third, we usually can't predict whether next year or the year after will be a good one or a bad one- that is, whether the **vital rates** will be more or less optimal year-to-year (whether a *population* will “get lucky”, so to speak). In population ecology this is called **environmental stochasticity**. The term **catastrophe** is reserved for stochastic environmental events that cause major population crashes or extinction. The term **bonanza** is sometimes used to describe very favorable stochastic environmental events that cause rapid population growth!

To model environmental stochasticity, we make the per-capita vital rates (e.g., the “*b*” or “*d*” terms or the elements of a projection matrix) **stochastic** (i.e., using a random number generator).

For this type of variability, we often use a **Normal distribution** or another continuous distribution like a **Lognormal distribution**, **Beta distribution**, or a **uniform distribution**. These random number generators are not (and should not be) constrained to be whole integers.

For example, let's imagine that annual per-capita birth rates (*b*) are generally around 1.25 but can vary between 0.8 and 1.7 depending on how favorable the weather is each year. Here is a distribution of birth rates from a Normal random number generator that approximately matches this description:

```
# Normal distribution
hist(rnorm(10000,mean=1.25,sd=0.15),main="",freq=F,xlab="Possibilities (annual birth rates)",ylab="Probabilities")
```

Or what if our mean per-capita birth rate is 1.1, with a standard deviation of 0.4:

```
hist(rnorm(10000,mean=1.1,sd=0.4),main="",xlab="Possibilities (annual birth rates)",freq = F,ylab="Probabilities")
```

Okay now let's get to the actual lab activity!

Exercise 1: Uncertainty!

Start with a basic exponentially growing population that looks something like this:

Set *Birth rate* equal to 0.3 and *Death rate* equal to 0.2. Set *initial abundance* to 20. Under the “Settings” menu set the model to run for 15 years. Make sure your *Population* stock can NOT go negative (this is a setting in the configurations panel). Hit “Simulate”- you should see *exponential growth*!

What if we have imperfect knowledge about birth rate? The data we have are consistent with a birth rate b as low as 0.15 and as high as 0.35. Run the model with the lowest and the highest possible birth rates. Now use the “Compare Results” tool (under the “Tools” menu in the upper right corner...) to visualize the range of possible population growth trajectories that would be possible given our *uncertainty* about the per-capita birth rate (i.e., plot the “worst-case scenario” and the “best-case scenario” in the same plot).

1a. Given the uncertainty we have about the true value for birth rate b , what is the lower and upper bound (worst case and best-case scenarios) for final abundances after 15 years? Considering this uncertainty, would it be reasonable to conclude that the population growth rate is positive in this population? Please justify your response. As part of your response, please upload the figure you generated using the ‘compare results’ tool.

Another way to do *uncertainty analysis* is to use a random number generator to represent uncertainty about a population vital rate. Specifically, we can use a *uniform distribution* to represent the range of uncertainty about a parameter value. In this case, we can define Birth rate as a **uniformly distributed** random variable with minimum of 0.15 and maximum of 0.35 (so that the random number generator produces values within this range). We can do this in InsightMaker in one of two ways: one way is to define birth rate b like this (within the ‘birth rate’ variable):

```
Rand(0.15, 0.35)
```

and the other is to define the birth rate b like this:

```
Fix(Rand(0.15, 0.35))
```

Use the “Sensitivity Testing” tool (in the “Tools” menu in InsightMaker, upper right-hand corner) to run each of these models 50 times using each of the two methods described above. Choose [Population] as the “Monitored Primitive” (otherwise use the default settings), and set the “Number of Runs” to 50. Run the Sensitivity Testing tool using the “Run Analysis” button and save a screenshot of the two resulting plots (one plot for each of the two methods).

The next three questions relate to comparing these two methods:

1b. Please upload the two plots you produced using the Sensitivity Testing tool (see above instructions)

1c. Examine the range (maximum abundance minus minimum abundance) of final abundances at year 15 in the two plots. Which method yielded the greatest uncertainty (largest range of possible values) about the final abundance? Try to explain why this method produced greater uncertainty about the final abundance than the other method? (this last part is challenging, but give it a try! It's not cheating if you try to read about what the "Fix" function does in InsightMaker!).

Let's think through the problem one more time- we are uncertain about the *true* value of the per-capita birth rate, b , for a rare species. The actual birth rate for this population could be anything from 0.15 to 0.35 - we really can't say! Given this uncertainty, we want to know *what the abundance will be after 15 years*.

1d. If you were tasked with evaluating with predicting the abundance of this population 15 years into the future, which of the two plots you generated in (1b) would be most appropriate for answering this question (i.e., which of the two plots is a better representation of our uncertainty about the future population size)? Explain your reasoning. [Hint: try to compare each of the two plots with the results from question 1a: that is, when you ran the model with the lowest possible value of b (worst case scenario) and the highest possible value of b (best case scenario) and used the "Compare Results" tool to plot these two results together]

Exercise 2: Demographic and Environmental Stochasticity

Demographic Stochasticity Set *Birth rate* in your model back to 0.3. *Change the initial abundance to 10 individuals*. Hit "Simulate"- make sure you still see exponential growth!

We will use a *Binomial distribution* to represent the total number of mortalities in the population. That is, we 'flip a coin' the same number of times as there are individuals in the population and if the coin comes up heads, then the individual dies. In this case we are using a biased coin- it only comes up heads 20% of the time! The *Binomial distribution* essentially represents the number of times heads came up. To do this in InsightMaker, use the following formula for the *Deaths* flow:

```
RandBinomial([Population], [Death rate])
```

That is, the number of deaths is equal to the number of "coin flips" that come out heads if the probability of getting heads is equal to [Death rate] and the number of coin flips is equal to [Population].

For the total number of births, we will use the *Poisson* distribution. The Poisson distribution is often used to represent the total number of births ([Births] flow), because there could plausibly be more births than there are individuals currently in the population (e.g., if all individuals have two offspring!). However, the maximum number we could draw from a binomial distribution is the total number of individuals. To do this in InsightMaker, use the following formula to represent the total number of births in the population:

```
RandPoisson([Population]*[Birth rate])
```

That is, the number of births is a Poisson-distributed random number with mean equal to [Population]*[Birth rate].

2a. Provide the link to your InsightMaker model with demographic stochasticity, with settings changed so that the model will *run for 30 years*. Make sure you don't change this IM model after you submit it - if you need to change it later, then clone it and modify the cloned version!

Next, use the "Sensitivity Testing" tool (in the "Tools" menu, upper right corner) to run the model 50 times for 30 years with a starting abundance of 10 individuals. Choose [Population] as the "Monitored Primitive". Save a screenshot of the resulting plot. Next, change the initial abundance to 500 and re-run the "Sensitivity Testing" tool. Save a screenshot of the resulting plot.

2b. Upload the two plots you just generated using the 'sensitivity testing' tool (you must upload both plots to fully answer the question!)

2c. Use the two plots from (2b) to evaluate the following question: For which of the following is *demographic stochasticity* a more important driver of population dynamics and extinction risk: higher initial abundance or lower initial abundance? Explain your reasoning, referencing the plots you produced for 2b.

Environmental Stochasticity Set the *Births* flow back to the way it was specified before we added a random number generator ([Population]/[Birth rate]), and do the same for Deaths*. Set initial abundance back to 10.

We will use a *Normal distribution* to represent how the birth rate changes each year. This could represent climatic variability – “good years” and “bad years”. The *Normal distribution* is commonly used for this type of variability- it is characterized by an average value (**mean**) and a measure of variability or spread (**standard deviation**). To do this in InsightMaker, you can use the following formula for the *Birth Rate* variable:

`RandNormal(0.3, 0.25)`

That is, the annual birth rate in this population has a mean of 0.3 but varies annually with a standard deviation of 0.25.

Similarly, you can use the following formula for the *Death Rate* variable:

`RandNormal(0.2, 0.25)`

Note that InsightMaker automatically insures that the birth rate is not negative (in-flows cannot draw out of the stock) and that the mortality process is not adding to the population (out-flows cannot add to the stock). As always, make sure your [Population] stock is set so that it cannot go negative!

2d. Copy and paste the link to your InsightMaker model into TopHat (and clone the model if you think you might make changes later!).

Next, use the “Sensitivity Testing” tool (in the “Tools” menu, upper right corner) to run the model 50 times for 30 years with a starting abundance of 10 individuals. Choose [Population] as the “Monitored Primitive”. Save a screenshot of the resulting plot. Next, change the initial abundance to 500 and re-run the “Sensitivity Testing” tool. Save a screenshot of the resulting plot.

2e. Upload the two plots you just generated using the ‘sensitivity testing’ tool (you must upload both plots to fully answer the question!)

2f. Use the plots from (2e) above to evaluate the following question: For which of the following is *environmental stochasticity* a more important driver of population dynamics and extinction risk: higher initial abundance or lower initial abundance? Explain your answer.

Exercise 3: Minimum Viable Population

The aruba island rattlesnake, or Cascabel (*Crotalus durissus unicolor*), is the top predator on the island of Aruba, and primarily consumes rodents.

The Aruba island rattlesnake, as you might expect, occurs only on the island of Aruba.

The Aruba rattlesnake is listed as *Critically Endangered* by IUCN, and has several attributes that make it particularly susceptible to falling into the **extinction vortex**:

- Range is limited to the small island of Aruba
- Total abundance is estimated as 250 individuals
- Population has been declining due to:
 - loss and degradation of habitat (overgrazing, human encroachment, forest clearing)
 - human persecution

Consider the following scenario: you are tasked with determining the minimum viable population size (MVP) for the Aruba Island rattlesnake. We define the *minimum viable population* (MVP) as:

MVP: The abundance threshold below which the risk of extinction exceeds 5% over the next 50 years.

Here are the key model parameters! (note that much of this is simplified and/or made up entirely!)

- The starting abundance is 250 individuals.
- No age/stage structure!
- Mean per-capita birth rate b is 0.70 (per-capita birth rate)
- Mean per-capita death rate d is 0.69 (per-capita death rate)
- Density dependence:
 - Carrying capacity is 500 individuals.
 - Above carrying capacity, per-capita birth rate drops to 0.35
- Environmental stochasticity:
 - birth rate is approximately normally distributed with standard deviation of 0.15
 - death rate does not change year to year (it stays constant at 0.69 per year).
- Demographic stochasticity:
 - total births are Poisson-distributed
 - total deaths are Binomially distributed

3a. Set up an InsightMaker model to represent the above scenario. Copy the link to your InsightMaker model in your write-up. As always, clone your Insight to ensure that this model doesn't change after you submit it!

3b. Is the current population **viable**, under the criteria listed above? That is, is there a less than 5% risk of extinction over a 50-year time frame? **Hint:** use the *Sensitivity Testing* tool to run at least 200 replicates. Visualize the 90% quantile. For a viable population under our definition, the lower bound of the 90% confidence region (the region below which only 5% of simulation results fall- note that an additional 5% of simulations fall above the upper bound of the 90% confidence region, which is why it's called a 90% confidence region!) should be greater than zero at year 50 of the simulation.

3c. Find the **minimum viable population (MVP)**. (Note: you can refer to the "small population paradigm" lecture for more detail on the concept of Minimum Viable Population). Explain your reasoning, and provide one or two plot(s) to back up your answer.

By the way, you have now run your first PVA model!!

3d. (thought question) The Aruba island rattlesnake is limited to the small island of Aruba. This fact alone is one of the main reasons this species is listed as *Critically Endangered* under the IUCN Red List (the major global ranking of conservation status). Explain why small range size might generally be associated with high extinction risk.

Checklist for Lab 5 completion

- Please submit your responses *on top hat!*

Due Mar. 25 at midnight (11:59pm)

- Short answers, InsightMaker model URLs, and plots (where appropriate)
 - **Exercise 1**
 - * *Short answer (1a.)*
 - * *plots (1b.)*
 - * *Short answer (1c.)*
 - * *Short answer (1d.)*
 - **Exercise 2**
 - * *InsightMaker URL (2a.)*
 - * *plots (2b.)*
 - * *Short answer (2c.)*
 - * *InsightMaker URL (2d.)*
 - * *plots (2e.)*
 - * *Short answer (2f.)*
 - **Exercise 3**
